

Atomic Actions

Atomic actions

Atomic action: an action that either is executed in full or has no effects at all

- Atomic actions in distributed systems:
 - an action is generally executed at more than one node
 - nodes must cooperate to guarantee that
 - either the execution of the action completes successfully at each node or the execution of the action has no effects
- The designer can associate fault tolerance mechanisms with the underlying atomic actions:
 - limiting the extent of error propagation when faults occur and
 - localizing the subsequent error recovery

J. Xu, B. Randell, A. Romanovsky, R.J. Stroud, A.F. Zorzo, E. Canver, F. von Henke. Rigorous Development of a Safety-Critical System Based on Coordinated Atomic Actions. In FTCS-29, Madison, USA, pp. 68-75, 1999.

An example: Transactions in databases

- Transaction: a sequence of changes to data that move the data base from a consistent state to another consistent state.
- A **transaction** is a *unit* of program execution that accesses and possibly updates various data items
- Transactions must be an atomic action:
all changes are executed successfully or data are not updated

Transactions in databases

Transaction T

T can access data at distinct nodes : distributed transaction

Transactions in databases

COMMIT

Termination with success of the transaction

All operations are executed and changes to the database are persistent

Transfer of 50 from account A to account B

t: begin transaction

```
UPDATE account  
SET balance=balance + 500  
WHERE account_number=45;
```

```
UPDATE account  
SET balance=balance - 500  
WHERE account_number=35;
```

commit

end transaction

Transactions in databases

ABORT or ROLLBACK

abort of the transaction

None operation is executed

Transfer of 50 from account A to account B. Abort if balance of A less than 500.

t: begin transaction

UPDATE account

SET balance=balance + 500 WHERE account_number=45;

UPDATE account

SET balance=balance – 500 WHERE account_number=35;

SELECT balance INTO V FROM account WHERE account_number=35;

if V >= 0 then commit else abort;

end transaction

Transactions in databases and failures

Transaction T

- 1) A failure before the termination of the transaction, results into a rollback (abort) of the transaction
- 2) A failure after the termination with success (commit) of the transaction must have no consequences

Banking application

Account =(account_name, branch_name, balance)

t1: distributed transaction (access data at different sites)

t1: begin transaction

UPDATE account

SET balance=balance + 500

WHERE account_number=45;

UPDATE account

SET balance=balance - 500

WHERE account_number=35;

commit

end transaction

t1

t11: UPDATE account

SET balance=balance + 500

WHERE account_number=45;

site1

t12: UPDATE account

SET balance=balance - 500

WHERE account number=35;

site2

Atomicity requirement

- **Atomicity requirement**
 - if the transaction fails after the update of 45 and before the update of 35, money will be “lost” leading to an inconsistent database state
 - the system should ensure that updates of a partially executed transaction are not reflected in the database

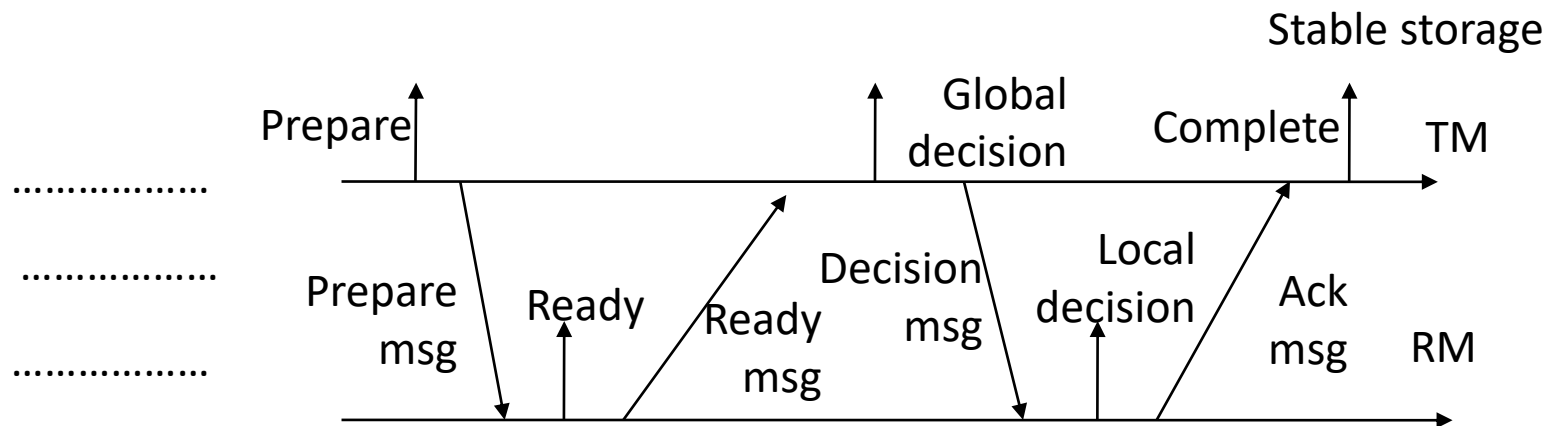

A main issue: atomicity in case of **failures of various kinds, such as hardware failures and system crashes**

- Atomicity of a transaction:
Commit protocol + Log in stable storage + Recovery algorithm

A programmer assumes atomicity of transactions

Two-phase commit protocol

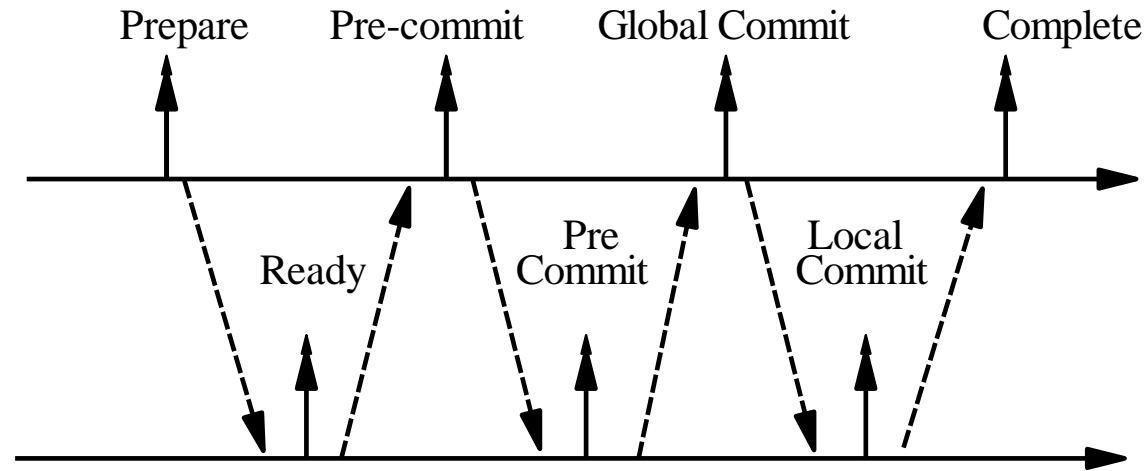

- One transaction manager TM
- Many resource managers RM
- Log file (persistent memory)
- Time-out

Tolerates: loss of messages
crash of nodes

Uncertain period:
if the transaction manager crash, a participant with Ready
in its log cannot terminate the transaction

Three-phase commit

Precommit phase is added. Assume a permanent crash of the coordinator. A participant can substitute the coordinator to terminate the transaction.

A participant assumes the role of coordinator and decides:

- Global Abort, if the last record in the log Ready
- Global Commit, if the last record in the log is Precommit

Recovery and Atomicity

Physical blocks: blocks residing on the disk.

Buffer blocks: blocks residing temporarily in main memory

Block movements between disk and main memory through the following operations:

- **input**(B) transfers the physical block B to main memory.
- **output**(B) transfers the buffer block B to the disk

Transactions

- Each transaction T_i has its private work-area in which local copies of all data items accessed and updated by it are kept.
- perform **read**(X) while accessing X for the first time;
- executes **write**(X) after last access of X .

System can perform the **output** operation later.

Let B_x denote block containing X .

output(B_x) need not immediately follow **write**(X)

Data Access

Recovery and Atomicity

- Several output operations may be required for a transaction
- A transaction can be aborted after one of these modifications have been made permanent (transfer of block to disk)
- A transaction can be committed and a failure of the system can occur before all the modifications of the transaction are made permanent
- To ensure atomicity despite failures, we first output information describing the modifications to a Log file in stable storage without modifying the database itself

Log-based recovery

Log file

Records in the log file:

Start:	$\langle T_1 \text{ start} \rangle$		
Update:	$\langle T_1, C, 700, 600 \rangle$	previous value:700	new value 600
Commit:	$\langle T_1 \text{ commit} \rangle$		
Abort:	$\langle T_1 \text{ abort} \rangle$		

DB Modification: an example

Log	Write	Output
$\langle T_0 \text{ start} \rangle$		
$\langle T_0, A, 1000, 950 \rangle$		
	$A = 950$	
$\langle T_0, B, 2000, 2050 \rangle$		
	$B = 2050$	
		Output(B_B)
$\langle T_0 \text{ commit} \rangle$		
$\langle T_1 \text{ start} \rangle$		
$\langle T_1, C, 700, 600 \rangle$		
	$C = 600$	
		Output(B_C)

DB Modification: concurrent transactions

Log	Write	Output
$\langle T_0 \text{ start} \rangle$		
$\langle T_0, A, 1000, 950 \rangle$		
	$A = 950$	
$\langle T_0, B, 2000, 2050 \rangle$		
	$B = 2050$	
		Output(B_B)
$\langle T_1 \text{ start} \rangle$		
$\langle T_0 \text{ commit} \rangle$		
$\langle T_1, C, 700, 600 \rangle$		
	$C = 600$	
		Output(B_C)

CRASH

Recovery actions

- undo (T_1) C is restored to 700
- redo (T_0) A reset to 950
B reset to 2050

Checkpointing

CHECKPOINT operation:

output all modified buffer blocks of committed transactions to the disk

CK(T_i, \dots, T_k) record in the Log, where T_i, \dots, T_k are the transactions active at the checkpoint

Checkpointing

To Recover from system failure:

- consult the Log
- redo all transactions in the checkpoint or started after the checkpoint that committed;
- undo all transaction in the checkpoint or started after the checkpoint that are not committed

Recovery algorithm

<T₀ start>
<T₀, A, 0, 10>
<T₀ commit>
<T₁ start>
<T₁, B, 0, 10>
<T₂ start>
<T₂, C, 0, 10>
<T₂, C, 10, 20>
<checkpoint {T₁, T₂>
<T₃ start>
<T₃, A, 10, 20>
<T₃, D, 0, 10>
<T₃ commit>
crash

Redo={} Undo={}

Scan the Log backward until checkpoint:
<T commit> -> add T to Redo
<T start> if T is not in Redo, add T to Undo

For each T active at the checkpoint,
if T is not in Redo, add T to Undo

Redo={T3} Undo={T1, T2}

Redo={T3} Undo={}

Redo={} Undo={}

Log file

Log file in a stable storage

Moreover:

- before the commit of a transaction,
save the block of the Log file containing the records of the transaction on disk

- before updating the database,
save the block of the Log file containing the update record on disk

It is always possible to execute Undo and it is always possible to execute Redo of a transaction if needed

Atomic actions

Advantages of atomic actions:

a designer can reason about system design as

- 1) no failure happened in the middle of a atomic action
- 2) separate atomic actions access to consistent data
(property called “serializability”, concurrency control).
